Abstract: In order to ascertain and measure dedicated aspects of social and technical systems 'maturity', a wide range of maturity assessment models have been developed by both, practitioners and academics over the past years. In spite of its broad proliferation, the concept has not been untroubled by criticism. Unnecessary bureaucracy, poor theoretical foundation, and the impression of a falsified certainty to achieve success are just a few examples for that.

As there is still a significant lack of knowledge on how to design theoretically sound and widely accepted maturity assessment models, it is the aim of this paper to discuss the typical phases of maturity model development and application by taking a design science research perspective.

Given that both, development and application are intimately connected, different decision parameters are identified that are relevant in respect to rigour and relevance of the maturity assessment model.

Keywords: assessment models; change engineering; design decisions; design principles; design science research; maturity models.

Reference to this paper should be made as follows: Mettler, T. (2011) 'Maturity assessment models: a design science research approach', Int. J. Society Systems Science, Vol. 3, Nos. 1/2, pp.81-98.

Biographical notes: Tobias Mettler received his PhD in Business Information Systems from the University of St. Gallen. He is a Senior Researcher at SAP Research, Campus-based Engineering Center (CEC) St. Gallen, Switzerland. His research interests include issues related to design science research, systems analysis, electronic commerce, and electronic healthcare.

1 Introduction

The concept of maturity assessment models is increasingly being applied within the field of information systems (IS) and management science, both as informed approach for continuous improvement (Paulk et al., 1993; Ahern et al., 2004) or as means of self or third-party assessment (Hakes, 1996; Fraser et al., 2002). Since the initial finding in the 1970s (Gibson and Nolan, 1974; Crosby, 1979), a multiplicity of different instantiations have been developed in science and practice. The popularity of maturity assessment models and other normative models like Six Sigma or the EFQM excellence model (cf. Pries-Heje and Baskerville, 2003) was especially intensified by the introduction of the
capability maturity model (CMM) in the late 1980s and its successors ISO/IEC 15504 also known as SPICE (software process improvement and capability determination) and BOOTSTRAP (Haase et al., 1994; Kuvaja, 1999). However, as the organisations constantly face the pressures to obtain and retain competitive advantage, invent and reinvent new products and services, reduce costs and time to market, and enhance quality at the same time, the need for and the development of new maturity models will certainly not diminish given that they assist decision makers to balance these sometimes divergent objectives on a more or less comprehensive manner. Furthermore, by incorporating formality into the improvement activities, decision makers can determine if the potential benefits have been realised or not. Fraser and Vaishnavi (1997, p.97) state that:

“Conflicts of interest can be avoided by using a measurement model developed externally to the organisation.”

Nonetheless, the concept has not been untroubled by criticism. For instance, Pfeffer and Sutton (1999) argued that the purpose of maturity assessment models is to identify a gap which can then be closed by subsequent improvement actions. However, lots of these models do not describe how to effectively perform these actions. This ‘knowing-doing gap’ can be very difficult to close, even when the decision makers know what to do. On the other hand, when exclusively focusing on the processes and objects assessed by these models, a kind of ‘falsified certainty’ is given to the decision makers. For example, CMM has been criticised because of its overemphasis on the process perspective and its disregard on people’s capabilities (Bach, 1994). Besides that, a too strong focus on formalisation of improvement activities accompanied by extensive bureaucracy can hinder people from being innovative (Herbsleb and Goldenson, 1996). The most important point of critique on maturity assessment models is, however, its poor theoretical basis (Biberoglu and Haddad, 2002). Most of the models base on ‘good practice’ or ‘success factors’ derived from projects that have demonstrated favourable results to an organisation or an industry sector. Moreover, data for an appraisal frequently depends on the people being asked (also referred to as key informant bias). Thus being compliant with the maturity assessment model would not necessarily guarantee that an organisation would achieve success. There is no agreement on a ‘one true way’ to assure a positive outcome (Montoya-Weiss and Calantone, 1994). According to de Bruin and Rosemann (2005) the reasons for these sometimes ambiguous results of maturity assessment models lies in the insufficient emphasis on testing the models in terms of validity, reliability and generalisability and on the little documentation on how to develop and design such a model. On that account, de Bruin and Rosemann describe in their work a first design methodology (first continuative thoughts have been made by the author as well in Mettler (2009). However, as the approaches for developing and evaluating design science research (DSR) significantly advanced in the last few years, it is the aim of this paper to engross the thoughts in two directions. First, from a developer’s perspective, we want to detail the seminal work of de Bruin and Rosemann (2005) by presenting particularised decision parameters for building and testing a maturity assessment model. Second, we want to extend this one-sided reflection by the user’s perspective, showing all phases required for successfully implementing a maturity assessment model in the social context.

In order to achieve this goal, the paper is organised as follows. First, we give a definition of the term ‘maturity’ and describe the possible dimensions of improving the levels of maturity in social systems. The section that follows is dedicated to the
clarification of the form and function of maturity assessment models and its foundation within DSR. Subsequently, common steps in designing maturity models are presented. In the section that follows, based upon the experience of developing an own maturity assessment model, we then discuss the most important decision parameters from a designer’s and the user’s perspective. Finally, we present some concluding remarks and offer some suggestions for future research endeavours.

The targeted audience of this contribution are practitioners and scientists generally interested in the topic of systems analysis and the evolution of systems. However, the paper is specially focussed on the evolution of IS, as most of the research conducted on maturity assessment models originates from this discipline.

2 Defining maturity in social systems

2.1 Fractions of maturity

According to Soanes and Stevenson (2006), ‘maturity’ generally can be defined as:

“The state of being complete, perfect or ready.”

Maturity thus implies an evolutionary progress in the demonstration of a specific ability or in the accomplishment of a target from an initial to a desired or normally occurring end stage.

In the constituent literature about maturity assessment models the term ‘maturity’ is in most instances reflected on a one-dimensional manner, either focussing on:

1 process maturity, i.e., to which extent a specific process is explicitly defined, managed, measured, controlled, and effective (Paulk et al., 1993; Fraser and Vaishnavi, 1997)

2 object maturity, i.e., to which extent a particular object like a software product, a machine or similar reaches a predefined level of sophistication (Gericke et al., 2006), or on

3 people capability, i.e., to which extent the workforce is able to enable knowledge creation and enhance proficiency (Nonaka, 1994).

The commonly used basis for assessing maturity in social systems are therefore people/culture, processes/structures, and objects/technology (in the following referred to as maturity factors). Weinberg (1992) was the first of a series of authors who delineated their strong dependency and effect on maturity with respect to software engineering. However, as mentioned already, their mutual influence is not always given and other perspectives may have an impact on the maturity of social systems as well (Wang, 2008).

Figure 1 thus illustrates a possible path of maturity progression: In the first case, the level of sophistication is increased for all the three maturity factors. This can be designated as the ideal case and is obtained when the model designed for reproducing the state of maturity likewise considers an improvement of object, process, and people abilities (e.g., learn the workforce how to collect customer requirements in a standardised manner by using standardised means). In the second case, only two factors are enhanced, notably object and process maturity (e.g. using a customer relationship management system instead of writing the customer requirements into unstructured documents). And
finally, maturity can be enhanced in one direction only (e.g., using a notebook to collect the data directly at the customer’s site). Understanding these different ways of progressing the level of maturity is a crucial task in the development of a maturity assessment model and especially important when testing the model with respect to its validity.

Figure 1 Different ways of progressing the level of maturity

2.2 Relation between maturity and diffusion

Another way to reflect maturity in social systems can be found in the seminal work of Rogers (1962) and Utterback (1971) on the emergence and diffusion of innovations. Diffusion research centres on the conditions, which increase or decrease the likelihood that an idea, product or practice will be adopted. Diffusion is thereby understood as (Rogers, 1962):

“The process by which an innovation is communicated through certain channels over a period of time among the members of a social system.”

Innovations either can be categorised as product innovations, i.e., the involvement of a new or improved object whose characteristics differ significantly from previous ones, or as process innovations, i.e., the involvement of a new or significantly improved practices to enhance production and/or delivery of objects (OECD, 1997). In both cases the difference in the characteristics to the prior solutions may emerge due to the application of new technologies, knowledge or materials. The enhancement of people’s capabilities is thus implicitly presupposed. Nevertheless, the theories of emergence and diffusion of innovations reveal interesting conditions with respect to the understanding and development of maturity in social systems (and the respective models for reproducing it).
According to Utterback and Abernathy (1975) the progress of a particular innovation follows an s-curve (cf. left hand side of Figure 2). As time goes by, innovation (mainly originating from many minor product or process improvements) passes through different stages of maturity. Of particular interest is thereby the disruptive phase where a dominant design of a solution (i.e., a general agreed standard or best practice) becomes evident. However, dominant designs may not be better than other designs, but acceptance of an innovation will be on peak. As regards to the development of maturity models the cognition of the state in which an innovation is situated is thus extremely important, especially when the model is prescriptive. For instance, when focussing on the assessment of emerging innovations the levels of maturity may be extremely uncertain given that no dominant design is found already. Recommended improvement activities therefore probably will be estimated as speculation. On the other hand, when concentrating on mature innovations the levels of maturity are clear but the potential for improvement is only marginal. In such a case the results from an appraisal may be understood as ‘bureaucracy’ or ‘platitude’ since no substantial benefits may be gained. A similar train of thoughts can be made when considering the diffusion of innovations (cf. right hand side of Figure 2). When using too fundamental or forward-looking criteria for the maturity assessment of an organisation, the application of the model will show an accumulation of the results on a predefined sophistication level (e.g., Hayes and Zubrow, 1995) discovered that 73% of the assessed organisations between 1987–1994 were stuck in the CMM-level 1 because the requirements of the process area ‘project management’ were far too hard to meet). Thus when defining the levels of maturity for a particular domain, a trade-off between the state of an innovation’s uncertainty and its actual diffusion (which assists in predicting whether and how an innovation will be successful) has to be considered in order to guarantee ‘useful insights’ (i.e., trustworthy but not too obvious improvement activities) from the application of the model.
individual, group, organisation and market perspective) by developing and verifying theories (March and Smith, 1995), design oriented research aims at building and evaluating ‘artificial solutions’, in order to extend existing capability limitations (Hevner et al., 2004). According to Hevner et al., (2004) the construction and evaluation of these solutions can be reflected on a generic level, focusing primarily on the design research process and on creating standards for its rigour (by some authors designated as ‘science of design’ (Cross, 2001) or ‘design science’ (McKay and Marshall, 2007) or on a specific level, aiming at creating artefacts (i.e., design research products) to concrete classes of relevant problems by using rigorous scientific methods for its construction and evaluation [according to Gericke and Winter (2008) also referred to as ‘design research’]. March and Smith (1995) differentiate:

1 constructs (the language to specify problems and solutions)
2 models (the representation of the identified problems and future solutions)
3 methods (the procedure how to solve these problems and develop the future solutions)
4 instantiations (the physical conversion as proof-of-concept of the prior artefacts) as unique artefact types.

This understanding has been broadly adopted by way of example in Hevner et al. (2004), Peffers et al. (2006) and Vahidov (2006). However, some scholars demand an enlargement of this classification by including ‘design theories’ as a fifth artefact type in order to provide a sounder basis for arguing for the rigour and legitimacy of design-oriented research [e.g., Walls et al. (1992), Venable (2006b), Gregor and Jones (2007)]. Hence, the question raises what artefact type a maturity assessment model is associated with: a model, a method, or a theory? We consider each of these three perspectives before describing how to develop a maturity assessment model in the subsequent section.

3.1 Model versus method

As to Wand et al. (1995, p.285) modelling normally in IS is applied:

“[…] in the analysis stage of systems development when abstract models of the represented system and its organizational environment are created.”

According to Mylopoulos (1992, p.51) models generally represent a formal description of:

“[…] some aspects of the physical or social reality for the purpose of understanding and communicating.”

Depending on the notion of the representation, they either are descriptive (i.e., they give an unprejudiced reproduction of some aspects of reality), explanatory (i.e., they deliver a depiction of causal connections to better understand reality) or predictive (i.e., they recommend an efficient solution state of a future reality). However, no matter the kind of form, all of them reflect the state of a particular application domain whether it is the exact description of the current situation or a suggestion for a more efficient or ideal target state.

In contrast, as to Brinkkemper (1996, p.275) methods are used:
“[…] to perform a systems development project, based on a specific way of thinking, consisting of directions and rules, structured in a systematic way in development activities with corresponding development products.”

Consequently, methods are systematic (i.e., they deliver rules on how to act and instructions on how to solve problems), goal-oriented (i.e., they stipulate standards on how to proceed or act to achieve a defined goal), and repeatable (i.e., they are inter-subjectively practicable) (Braun et al., 2005). As opposed to models where state descriptions (what) are the root of the matter, methods rather focus on the specification of activities (how).

Figure 3  Positioning of maturity models in-between models and methods

Maturity assessment models, although numerously developed and applied in the past years, lack a clear definition and contextualisation. When reviewing the constituent literature, the current understanding of maturity assessment models tends to be somehow in-between the prior described artefact types, as they normally describe the typical behaviour exhibited by a person or organisation at a number of predefined levels of maturity for each of several maturity factors of the area under study (cf. Section 2) and of the procedures which might be regarded as appropriate to reach the next level (cf. Figure 3). In summary, they combine state descriptions (i.e., the maturity levels) with a number of key practices (i.e., the improvement activities) to address a series of goals (they should not be confused with maturity grids, which aim at illustrating the number of levels of maturity in a simple, textual manner and thus are comparable with Likert-scale questionnaires with anchor phrases (cf. Fraser et al., 2002).

3.2 Theory versus (IT-) artifact

Different semantics and individual views on theory and theorising in DSR complicate the fixation of what is understood as design theory. Gregor and Jones (2007, p.322) define design theories as:

“[…] principles inherent in the design of an IS artefact that accomplishes some end, based on knowledge of both IT and human behaviour.”

According to them, eight separate components can be differentiated:
purpose and scope (i.e., the meta-requirements of the problem solution)
constructs (i.e., the entities of particular interest)
principles of form and function (i.e., the meta-description of the problem solving)
artefact mutability (i.e., possible state changes in the design of the solution)
testable propositions (i.e., truth statements about the theory)
justificatory knowledge (i.e., underlying kernel theories)
principles of implementation (i.e., concrete description of the problem solving process)
an expository instantiation (i.e. the physical implementation).

Whereas the first six components are mandatory, the last two are optional parts of a design theory.

In reference to maturity assessment models it is difficult to take a firm stand whether they are theory or not. Depending on the maturity and diffusion of the studied phenomenon (cf. Figure 2) the ways in progressing the levels of maturity may be clear (mature innovations) or extremely uncertain (emerging innovations). This has an extraordinary influence on the accomplishment of the mentioned theory requirements. When building a maturity assessment model for a highly innovative phenomenon, justificatory knowledge to be based upon is weak or missing and principles of form and function are unclear as no dominant design prevails. Furthermore, the required cases to derive the maturity levels and recommendations may be missing as well. As a consequence, testable propositions will probably remain untested since no person or firm has accomplished the final maturity requirements. Therefore the resulting maturity model is rather an artefact than a theory. On the other hand, if the studied phenomenon is mature, the knowledge base for building and the cases for testing the design propositions are available and design mutability is more or less manageable. Accordingly, all necessary and sufficient conditions for building a design theory are given for a maturity model addressing a ‘mature’ domain.

4 Research design

In contrast to for example reference process models (e.g., Höhnel et al., 2007; Seidel et al., 2006; vom Brocke, 2007), little is known about the design of maturity assessment models. An extensive search within the relevant literature demonstrated that the great part of the developed maturity assessment models does not disclose its research method and their underlying design decisions. However, the externalisation of this knowledge has an important consequence. As Alexander (1964) stated:

“The use of logical structures to represent design problems [...] brings with it the loss of innocence. A logical picture is easier to criticize than a vague picture since the assumptions it is based on are brought out into the open. Its increased precision gives us the chance to sharpen our conception of what the design process involves.”
To our knowledge, there only exist a few articles that do expatiate the research method how to theoretically develop a maturity assessment model. In fact, our literature review simply yielded three different design methodologies. Thereof two use a top-down (de Bruin and Rosemann, 2005; Becker et al., 2009; Knackstedt et al., 2009) and one a bottom-up approach (Mettler, 2010) to develop a maturity model.

Although different in the details of the model definition (a top-down approach first defines the maturity levels and then the assessment items, conversely the bottom-up approach), we can see that the reviewed methodologies base (to some extent) on common design steps (cf. Table 1).

The design of maturity assessment models is intimately connected with the application phase, too. It is therefore our opinion not to analyse both perspectives concurrently (cf. Figure 4).

All of the three presented design methodologies constitute, without doubt, helpful frameworks for building and evaluating maturity assessment models. However, as the nature of the methodologies is largely generic, the developers and users of maturity assessment models are left alone with essential decisions how to design or apply these kinds of models. Hence, based upon the author’s experience of developing a maturity model (Mettler and Rohner, 2009), the most relevant decision parameters from a developer’s as well as user’s perspective are presented in the subsequent section.

Figure 4 Two sides of the same coin? Development and application cycle of maturity assessment models

5 Development and application of maturity assessment models

5.1 The developer’s perspective

Developing maturity models by conducting design-oriented research means finding solution patterns for important unsolved problems or giving advice in solving problems in more effective or efficient ways (Hevner et al., 2004). As DSR is a problem-oriented approach, the development cycle is usually initiated by a ‘need and require intention’ (Purao, 2002). However, according to Järvinen (2007) a business need is not necessarily required but a new opportunity as “opportunity-based innovation can have a great economic value”. The complete development cycle consists of four phases:

1. define scope
2. design model
3. evaluate design
4. reflect evolution (cf. Figure 4).
In the ‘define scope phase’ the developer is faced with the most important design decisions (cf. Table 2). First, as it will influence all the following decision parameters, the focus of the phenomenon to be studied is set. By either choosing a generalistic (e.g., learning organisations as per Aggestam, 2006) or a more specific subject-matter (e.g., risk management (RM) for medical device companies as per Burton et al., 2006) the breadth of the maturity model is defined. On the other hand, the level of analysis conditions the maturity model’s ‘operating altitude’. For instance RM can be explored on the group level (e.g., decision-making within a particular department of the firm), on the organisation level (e.g., RM integrated as part of corporate governance), on the inter-organisational level (e.g., collaborative RM between the medical device company and the health care organisations) or on a more global and societal level (e.g., societal safety aspects of RM). Furthermore, as ‘utility’ is in the centre of DSR interest (Hevner et al.,

Table 2 Decision parameters during the development of a maturity assessment model

In the ‘define scope phase’ the developer is faced with the most important design decisions (cf. Table 2). First, as it will influence all the following decision parameters, the focus of the phenomenon to be studied is set. By either choosing a generalistic (e.g., learning organisations as per Aggestam, 2006) or a more specific subject-matter (e.g., risk management (RM) for medical device companies as per Burton et al., 2006) the breadth of the maturity model is defined. On the other hand, the level of analysis conditions the maturity model’s ‘operating altitude’. For instance RM can be explored on the group level (e.g., decision-making within a particular department of the firm), on the organisation level (e.g., RM integrated as part of corporate governance), on the inter-organisational level (e.g., collaborative RM between the medical device company and the health care organisations) or on a more global and societal level (e.g., societal safety aspects of RM). Furthermore, as ‘utility’ is in the centre of DSR interest (Hevner et al.,
considerations about the novelty of the subject (e.g., focusing on a mature phenomenon but trying to give advice in a more effective or efficient way or solve new emerging problems), the audience (tailoring the model to the particular needs of a management-oriented or a technology-oriented audience, or both), and the dissemination of the model (open to the specified audience or exclusive access only) have to be taken as well.

When the scope is set, the actual maturity model is built in the ‘design model phase’. As described in Section 2, it is extremely important to have a clear understanding of what is meant by ‘maturity’. Having a process-focused understanding of maturity implies to centre on activities and work practices (e.g., inputs and outputs of specified tasks) in order to define more effective procedures. With an object-focused understanding, the features of work products (e.g., functional and non-functional requirements) are investigated in order to enhance their mode of operation. When comprehension of ‘maturity’ is inclined to people’s skills and proficiency, the emphasis of the model lies more on the soft capabilities (e.g., people’s feelings and behaviour). Through this clarification of ‘maturity’, the goal function of the model (i.e. the way how maturity is progressed) is tacitly influenced (e.g., efficiency is almost always the underlying goal of process-oriented maturity). Also it remains still important to ponder whether the progress of maturity is one-dimensional (i.e., solely focusing on one target measure like efficiency) or multi-dimensional (i.e., focusing on multiple, sometimes divergent goals or competitive bases). If the goal function is clear, the nature of the design process (e.g., theory-driven versus practitioner-based or a combination of both) has to be determined in order to identify the knowledge base for deriving the maturity levels, the metrics, and the corresponding improvement recommendations. This decision is of particular interest as it has a major influence on the choice of the research methods to be used (e.g., literature review versus focus group discussions) and on the scientific and practical quality of the resulting design product. The latter is also determined by the shape of the design product (whether it is a pure textual description of the form and/or functioning of the maturity model or if it is instantiated as software assessment tool), the application method (whether the data collection is based upon a self or a third-party assessment), and the setting of the respondents for data collection (e.g., management, staff, business partners or a combination). Certainly, design process and product is also strongly constrained by the skills of the developers and the resources available for building the model (e.g., academic and business partners, research and programming skills).

The ‘evaluate design phase’ is concerned with the verification and validation of the designed maturity model. In line with Conwell et al. (2000) verification is the process of determining that a maturity model represents the developer’s conceptual description and specifications with sufficient accuracy and validation is the degree to which a maturity model is an accurate representation of the real world from the perspective of the intended uses of the model. In doing so, Pries-Heje et al. (2008) state that it is a purposeful strategy to define the subject (what), the time-frame (when), and the method for evaluation (how). As regards to the subject of evaluation it is possible to test the design process (i.e., the way the model was constructed) or the design product (i.e., the model itself). In order to counter the before mentioned criticism on the rigour of maturity models, it is our opinion that both should be subject of the evaluation. Then, the developer has to decide the point in time of evaluation (ex-ante versus ex-post). This – in combination with the novelty of the topic and the availability of the required
respondents – has an influence whether artificial (e.g., experiment) or naturalistic (e.g.,
case study) methods are used.

At last, in the ‘reflect evolution phase’, the design mutability of the model is
contemplated. This is of particular importance – but for all that sometimes neglected – as,
on the one hand, the maturity of the phenomenon under study is growing and therefore
the model’s solution stages and improvement activities have to be refaced from time to
time (e.g., modify requirements for reaching a certain maturity level due to the
emergence of new best practices and technologies), on the other hand, changes in the
form and function are needed to ensure the standardisation and global acceptance of the
model (e.g., amend the model schema from a CMM to a CMMI-compliant structure).
Therefore basically all-or-none can be subject of evolution; that is the form (e.g., the
underlying meta-model or model schema of the maturity model), and the functioning
(e.g., the way how maturity is assessed). Finally, it has to be determined whether
evolution is a non-recurring or continuous matter and how change is ‘produced’. For
instance, modifications can be openly induced by model users or exclusively by the
developer himself.

5.2 The user’s perspective

The successful application of a maturity model normally passes through four phases:

1. select model
2. prepare deployment
3. apply model
4. take corrective actions (cf. Figure 4).

In contrast to the maturity model development cycle, the application cycle always starts
with a business need by reason that the application of a maturity model always is
associated with extensive costs. Taking the user’s perspective the following decision
parameters are identified (cf. Table 3).

The ‘select model’ phase starts with a broad search for potentially applicable maturity
models with regard to the identified business need. As to date the knowledge base is poor
and a maturity model classification or reference database is missing, this can be a very
laborious endeavour. However, in order to limit the number of models found, criteria for
selection are needed. For instance, these can be the origin of the model (i.e., whether it
has its source from academia or practice), reliability (i.e., how well the maturity model
has been evaluated), accessibility (i.e., if it is free for use or not), practicality of
recommendations (i.e., whether the recommendations are problem-specific or more
general in nature and hence need more detailing), and the method of application (e.g.,
self-assessment or an appraisal by certified professionals). In addition, design mutability
(i.e., convertibility of model elements and ease of integration in existing organisational
model base) is important as well, since synergy effects in respect of training, appraisals
and improvement activities are left behind when applying multiple maturity models for
different problem domains that are not integrated within and across the organisation.
Ultimately, all these decision parameters yield to a suitable match with respect to cost
(e.g., time and financial expenses) and value (e.g., the ease with which the produced
results of the maturity model have a positive effect on business activities).

When a particular model is selected, the ‘prepare deployment phase’ begins. In this phase it is fundamental to find a potential sponsor or responsible for the appraisal. Additionally, formality of realisation has to be determined (e.g., rather informal appraisal versus formal assessment) and the corresponding application area and respondents must be located. Finally, training with the relevant stakeholders is conducted.

In the ‘apply model phase’ two basic decisions are identified. First, should the appraisal really be performed, and second, how many times it shall be executed. In the final ‘take corrective actions phase’, the appraisal results are critically reflected. It has to be decided whether the progress on maturity should be coupled or uncoupled of the regular target system of the organisation and whether the implementation of the improvement activities can be done on the fly or a specific project is needed and who should effect the corrective actions (e.g., the affected line organisation, the staff organisation, or external consultants).

6 Discussion

In order to evaluate our framework for reflecting the development and use of maturity assessment models either an artificial or a naturalistic evaluation is possible (Venable, 2006a). Artificial evaluation may be empirical or non-empirical, including techniques such as laboratory experiments, simulations, criteria-based analysis, theoretical
arguments, and mathematical proofs. On the other side, naturalistic evaluation is centred on studying the solution in its real environment, thus comprising techniques such as case studies, action-research, or survey studies.

In order to provide a proof of concept of the practicability of the proposed decision parameters, a two-step evaluation approach was conducted.

The artificial part of the evaluation started with the design of a maturity model for supplier relationship management and its instantiation by means of a software prototype (a more detailed description of the model features can be found in Mettler and Rohner, 2009).

On basis of the prototype, a naturalistic evaluation was conducted by asking practitioners to judge the maturity assessment model with regards to its quality of content, quality of instantiation, utility for personal decision making, and utility for the organisation (Mettler, 2010). In doing so, valuable inputs for extending and refining the prototype were obtained. Overall, the developed maturity assessment model received very good feedback from the respondents and, thus, allows us to corroborate the hypothesis that the specified decision parameters are, in some extent, useful for building sound and practical maturity assessment models.

As to the decision parameters for the application of maturity models, a third evaluation step is needed for demonstrating the applicability and utility of the decision parameters for applying maturity assessment models. For instance, the proposed decision parameters shall be used when planning a new assessment or selecting a particular assessment strategy. In doing so, it may be compared with other, more general decision parameters as described for example in Nielsen and Pries-Heje (2001). Hence, an ultimate statement related to the usefulness of the specified decision parameters from a user’s perspective cannot be made at that time yet.

7 Conclusions

With this paper, we introduced a definition of the term maturity and a contextualisation of the concept of maturity assessment models for social systems taking a DSR position. As knowledge on how to design theoretically sound and widely accepted maturity assessment models is lacking, we further proposed, on the basis of the work of de Bruin and Rosemann (2005), a phase model for both, development and application of such models. To illustrate their mutual interrelation, all relevant decision parameters for each phase are discussed. Therewith, and given that no uncriticised standard design methodology exists so far, we intended to contribute to a subject matter of social systems research, which in practice, because of its complexity, is widely recognised, while it is somehow neglected in research. However, the proposed phase model is limited in that it is only supported by few research experiences. Nevertheless, our findings may provide a basis for further research.

In order to generalise the findings so far, it is therefore necessary to incorporate experiences from other domains and to extensively test the propositions, for instance by developing own maturity assessment models or by investigating the user’s behaviour during the model application. Moreover, the identification of useful classification criteria for maturity assessment models and the development of a model base will serve practice as well as research.
